ABSTRACT

Outcomes for patients with advanced hepatocellular carcinoma (HCC) remain poor despite recent progress in drug development. Emerging data implicate FGF19 as a potential HCC driver, suggesting its receptor, FGFR4, as a novel therapeutic target. We evaluated fisogatinib (BLU-554), a highly potent and selective oral FGFR4 inhibitor, in a phase I dose-escalation/dose-expansion study in advanced HCC using FGF19 expression by immunohistochemistry as a biomarker for pathway activation. For dose escalation, 25 patients received 140 to 900 mg fisogatinib once daily; the maximum-tolerated dose (600 mg once daily) was expanded in 81 patients. fisogatinib was well tolerated; most adverse events were manageable, grade 1/2 gastrointestinal events, primarily diarrhea, nausea, and vomiting. Across doses, the overall response rate was 17% in FGF19-positive patients (median duration of response: 5.3 months [95% CI, 3.7–not reached]) and 0% in FGF19-negative patients. These results validate FGFR4 as a targetable driver in FGF19-positive advanced HCC.

STATEMENT OF SIGNIFICANCE

Fisogatinib elicited clinical responses in patients with tumor FGF19 overexpression in advanced hepatocellular carcinoma. These results validate the oncogenic driver role of the FGFR4 pathway in hepatocellular carcinoma and the use of FGF19 as a biomarker for patient selection.

INTRODUCTION

Hepatocellular carcinoma (HCC), the most common primary liver cancer, is a leading cause of cancer morbidity and mortality worldwide with 841,000 new cases and more than 781,000 deaths worldwide in 2018 (1,2); however, despite recent advances in drug development, the outcome for patients with advanced HCC remains poor. Currently approved treatments for HCC in the first-line setting include the multikinase inhibitors sorafenib and lenvatinib. Second-line treatments include the multikinase inhibitors cabozantinib and regorafenib, the anti-VEGF antibody ramucirumab, and the anti-PD1 antibodies nivolumab and pembrolizumab (3). Although anti-PD1 antibodies are associated with encouraging response durations, most patients do not achieve an objective response. With these available treatments, median progression-free survival (PFS) and overall survival (OS) remain in the ranges of 3 to 7 months and 9 to 13 months, respectively (4-10). Thus, there is a critical unmet need for improved novel treatments for HCC.

Emerging data implicate fibroblast growth factor (FGF) 19 as a potential HCC driver and suggest its receptor, the tyrosine kinase FGF receptor 4 (FGFR4), as a novel therapeutic target. FGF19 normally functions as an ileum-derived postprandial hormone that regulates bile acid synthesis and hepatocyte proliferation via signaling through FGFR4 and co-receptor klotho- β (KLB) (11). However, several studies demonstrated aberrant FGF19 expression in a subset of HCC, potentially implicating FGF19 as a driver of hepatocarcinogenesis (12,13). FGF19 overexpression in patients with HCC occurs via genomic amplification of the FGF19/CCND1 locus on chromosome 11q13.3 (~6% of cases) (13-15) or via epigenetic mechanisms that upregulate FGF19 mRNA/protein (~23% of cases) (16). In either case, aberrant expression of FGF19 may create an autocrine/paracrine signaling loop in which the ligand binds to FGFR4 and KLB and initiates downstream signaling that promotes HCC proliferation and survival. Preclinical data support this by showing that ectopic FGF19 expression in vitro promotes HCC proliferation, and transgenic FGF19 expression in mice causes HCC (17,18). Targeting FGFR4 with antibodies (19) or small molecule inhibitors (20) attenuates tumor growth in HCC preclinical models, demonstrating the therapeutic potential of this pathway. In a recent study, *FGF19* amplification was independently associated with shorter survival and a higher risk of recurrence in patients with HCC and was correlated with poor prognostic factors such as high α -fetoprotein and microvascular invasion (21).

We developed fisogatinib (BLU-554), a potent and highly selective oral FGFR4 inhibitor optimized for clinical use, and an accompanying immunohistochemistry (IHC) assay to detect aberrant FGF19 expression for use as a potential marker of pathway activation. A phase I first-in-human trial in patients with advanced HCC was conducted to assess the safety, pharmacokinetics (PK), pharmacodynamics (PD), and preliminary clinical activity of fisogatinib and to define the clinical utility of FGF19 IHC as a predictive marker of response.

RESULTS

Fisogatinib Selectively Inhibits FGFR4

Fisogatinib was designed to be a potent, highly selective, small-molecule inhibitor of FGFR4 (Fig. 1A). Fisogatinib covalently binds a unique cysteine residue found in FGFR4 (Cys 552; Supplementary Figure S1A), thereby conferring a very high degree of selectivity for FGFR4 over other FGFR family members (22) and across the kinome (Fig. 1B). This selectivity and potent inhibition of FGFR4 were particularly notable when compared with sorafenib, regorafenib, and the pan-FGFR inhibitor, BGJ398, which inhibit a broader range of targets across the kinome (Fig. 1B). Fisogatinib also has a high affinity for FGFR4 that is approximately 100-fold higher than its affinity for FGFR1 and almost 1000-fold higher than its affinity for FGFR2 and FGFR3 (22). Fisogatinib dose-dependently blocked the downstream signaling of FGFR4 in Hep3B cells that were further activated with exogenous FGF19 and in MDA-MB-453 cells with mutated and constitutively active FGFR4 (Supplementary Fig. S1B and C) (23). Conversely, fisogatinib did not affect the downstream components of FGFR1 in the lung carcinoma cell line DMS114 when stimulated with FGF2, further confirming the selectivity of this compound (Supplementary Fig. S1D).

To assess the potential utility of FGF19 IHC expression as a marker of pathway activation, we examined the activity of fisogatinib in FGF19 IHC-positive and IHC-negative HCC xenografts. Fisogatinib induced potent, dose-dependent tumor regressions in FGF19 IHC-positive xenografts (Fig. 1C). By contrast, FGF19-negative tumor lines were resistant to fisogatinib treatment (Supplementary Fig. S2A and B). Fisogatinib activity was independent of the level of IHC positivity and was comparable in models with (Hep3B) and without (LIX-066) *FGF19* genomic amplification. Tumor regressions were more pronounced with fisogatinib than with sorafenib (Fig. 1C).

FGF19 IHC as a Biomarker for Patient Selection

Because there is consistent expression of FGFR4 and KLB in normal liver and HCC samples (Supplementary Fig. S3A and B), we focused our diagnostic efforts on the variable expression of FGF19 in HCC. IHC was selected because it requires limited amounts of tissue, is available worldwide, and has the capacity to generate reliable and reproducible results with quick assay turnaround times. A central laboratory assay was developed for clinical trial use, and staining of $\geq 1\%$ of cells was chosen as an initial positivity cutoff based on concordance with FGF19 mRNA expression (Fig. 2A). Using this assay, we demonstrated FGF19 expression in a subset of HCC tissues but not in adjacent normal liver (Fig. 2B). Of 395 samples tested, 27% were positive for FGF19 staining $\geq 1\%$ above baseline. FGF19 positivity by IHC was well correlated with *FGF19* mRNA levels (Fig. 2A).

Patient Population and Disposition

This first-in-human study used a 3+3 dose-escalation followed by a maximum tolerated dose (MTD) dose-expansion design (Supplementary Fig. S4A). Additional patients could be enrolled to receive dose levels that were declared tolerable. Once-daily (QD) and twice-daily (BID) schedules were explored. For dose escalations, FGF19 tumor expression was assessed retrospectively. For dose expansion, FGF19 tumor expression was assessed prospectively to enroll FGF19 IHC-positive and FGF19 IHC-negative cohorts. A total of 115 patients were enrolled in the study (Supplementary Table S1). Most patients (90%) were on their second or later line of therapy; the median number of prior therapies in the total population was 1 (range, 0–5). On the QD schedule, 106 patients (25 patients in dose escalation; 81 patients in dose expansion), most of whom had been previously treated with sorafenib (85%), were enrolled (Supplementary Fig. S4A). In the QD dose escalation phase, patients were treated with 140 mg ($n = 3$), 280 mg ($n = 3$), 420 mg, ($n = 6$), 600 mg ($n = 6$), or 900 mg ($n = 7$); the starting dose was 140 mg. After completion of the QD dose escalation, a BID schedule was explored; the starting dose was 200 mg BID (400 mg total daily dose, $n = 6$), which was escalated to 300 mg BID (600 mg total daily dose, $n = 3$).

Of all 115 patients enrolled in the study, 63% were positive for FGF19 by IHC. A subset of 53 patients with FGF19-positive tumors by IHC who had available tissue was assessed for FGFR4 and KLB mRNA expression. Importantly, essentially all ($n = 51$, 96%) FGF19-positive patients in this study also showed FGFR4 and KLB expression by RNA sequencing

(Supplementary Fig. S4B), confirming FGFR4 pathway integrity. Most patients had metastatic disease and had previously been treated with surgery, transarterial chemoembolization, and systemic therapy, such as sorafenib or other multikinase inhibitors (Table 1). Infections from hepatitis B virus or hepatitis C virus were the most common HCC etiologies. Patients with FGF19 IHC-positive tumors were more likely to have α -fetoprotein (AFP) levels ≥ 400 ng/mL ($P = 0.002$) and trended towards being more likely to have macrovascular invasion ($P = 0.13$) than patients with FGF19 IHC-negative tumors, indicating that FGF19 positivity was correlated with poor prognostic factors, in line with a previous study (21).

Patients in the QD cohorts remained on treatment for a median of 2.1 months (range, 0.2–15.2 months), and patients in the BID cohorts remained on treatment for a median of 2.1 months (range, 0.2–19.6 months). At the time of the data cutoff, 5 patients (5%) continued treatment on the QD dosing schedule and none continued treatment on the BID dosing schedule. The most common reasons for discontinuing treatment in the total population were progressive disease (75%) and adverse events (AEs, 13%; Supplementary Table S2).

Safety

In the QD dose-escalation phase, no dose-limiting toxicities (DLTs) were observed in patients after 1 cycle of fisogatinib with doses of 140 to 600 mg. In the 900-mg cohort, 2 DLTs (1 case of grade 3 abdominal pain and 1 case of grade 3 fatigue lasting > 7 days) were observed (Supplementary Table S3). Therefore, 600 mg was considered the MTD and was selected for the dose expansion phase.

In the BID dose escalation, no DLTs were observed in the initial 3 patients enrolled in the 200-mg BID cohort. Subsequently, 1 DLT of grade 3 pulmonary edema was observed in 3 patients treated with 300-mg BID fisogatinib. Of 3 additional patients who received 200-mg BID fisogatinib, 2 DLTs of clinically intolerable grade 2 nausea, vomiting, and diarrhea were observed, indicating that the MTD had been exceeded at these dose levels. Because of less favorable tolerability observed with BID dosing (Supplementary Tables S4 and S5) and lower overall dose intensity relative to the QD schedule, a BID dose expansion was not pursued.

Across all dose levels in the QD dose escalation and dose expansion cohorts, 13 patients (12%) experienced AEs leading to discontinuation of fisogatinib, with 8 of 13 discontinuations being from AEs considered related to fisogatinib. These AEs included fatigue ($n = 4$), abdominal pain, alanine aminotransferase increased, aspartate aminotransferase

increased, blood bilirubin increased, diarrhea, and pyrexia ($n = 1$ each). The majority (53%) of treatment-related AEs in the QD cohorts were grade 1 or 2. The most common treatment-related AEs in patients treated with QD fisogatinib were diarrhea (74%), nausea (42%), and vomiting (35%), which are expected on-target toxicities related to enhanced bile acid secretion (Table 2). These AEs were manageable with supportive care and dose interruption or reduction. Grade ≥ 3 treatment-related AEs occurred in 46 patients overall (43%), with the most common being elevated aspartate aminotransferase (16/106, 15%) and alanine aminotransferase (12/106, 11%) levels. Grade ≥ 3 diarrhea, vomiting, and nausea occurred in 8 (8%), 4 (4%), and 2 (2%) patients, respectively. Serious AEs of any grade occurred in 46 patients (43%) in the QD dosing cohorts, with the most common being disease progression ($n = 5$), hepatic failure ($n = 4$), anemia ($n = 3$), elevated blood bilirubin ($n = 3$), pyrexia ($n = 3$), and vomiting ($n = 3$). There were no treatment-related deaths in the BID or QD dosing groups. Treatment-emergent grade 5 AEs were experienced by 10 patients in the QD dosing cohorts, and none were related to fisogatinib (Supplementary Table S6). Additional treatment-emergent AEs for the QD dosing cohorts are listed in Supplementary Table S6.

Pharmacokinetics and Pharmacodynamics in the Dose-Escalation Phase

To assess fisogatinib exposure in patients, blood was collected before dosing with fisogatinib and at prespecified time points following dosing on cycle 1, day 1 (C1D1) and on cycle 1, day 15 (C1D15). Following administration of single oral doses of fisogatinib ranging from 140 to 900 mg QD, the median time to peak concentration (T_{max}) ranged from 1.5 to 2 hours post-dosing (Fig. 3A). The mean plasma elimination half-life ($t_{1/2}$) of fisogatinib was 16.5 hours. Systemic exposure of fisogatinib increased in a dose-dependent manner after a single dose on C1D1 and repeat dosing on C1D15. There was no significant drug accumulation (accumulation ratio [Rac] ≤ 1.5) after repeat dosing of fisogatinib, consistent with the observed half-life. At C1D15, the steady state geometric mean (%CV; n) for the maximum plasma concentration (C_{max}) and area under the curve ($AUC_{0-\tau}$) of fisogatinib at the 600-mg QD dose was 8925 ng/mL (33.5%; $n = 70$) and 91,742 h \times ng/mL (42.0%; $n = 64$), respectively. This exposure to fisogatinib was within the expected therapeutic range based on nonclinical data in xenograft models, supporting 600 mg QD as the recommended phase II dose.

FGFR4 pathway activation by FGF19 promotes bile acid production from cholesterol (24). To study the effects of fisogatinib on FGFR4 pathway activity, fasting blood samples were collected from patients and assessed for plasma or serum cholesterol, bile acid precursors, and

FGF19. As would be expected from FGFR4 pathway inhibition, levels of plasma cholesterol were dose-dependently reduced after treatment, while levels of bile acid increased after treatment, reflecting derepression of bile acid synthesis. In addition, levels of serum FGF19 dose-dependently increased due to release of negative feedback (Fig. 3B–D).

Clinical Activity

Across 106 patients treated with QD dosing, 98 were evaluable for response assessments per RECIST v1.1 with measurable disease at baseline and at least 1 post-baseline radiographic response assessment. Sixty-six patients with FGF19-positive tumors were evaluable for response, and the overall response rate (ORR) in this population was 17% (11 of 66 patients), with 1 complete response (CR; 2%) and 10 partial responses (PRs, 15%; Fig. 4A, Table 3). Three patients remained in response at the time of data cutoff. One patient experienced a PR in the 280-mg cohort, 2 in the 420-mg cohort, and 7 in the 600-mg cohort; the patient who experienced a CR was in the 600-mg cohort. Responses were observed across a wide range of FGF19 IHC positivity (Supplementary Table S7). Eight of the 11 responders had received prior sorafenib. Radiographic tumor reduction and response per RECIST 1.1 were observed in 41% of patients with (*FGF19* FISH-positive) and without (*FGF19* FISH-negative) *FGF19* genomic amplification. Response typically occurred at the first radiographic assessment (2 months); the median duration of response (DOR) for responding patients with FGF19-positive tumors was 5.3 months (95% CI, 3.7 months–not reached; Fig. 4B, Table 3), and the median progression-free survival (PFS) was 3.3 months (95% CI, 2.1–3.7 months). Eight of the responding patients had responses > 6 months (Fig. 4C).

Of 34 patients who had FGF19-negative tumors or an unknown FGF19 status ($n = 29$ FGF19 negative; $n = 5$ unknown), 32 were evaluable for response assessments. Per RECIST v1.1, the ORR in these patients was 0% (0 of 32 patients), with 16 patients (50%) having stable disease and 16 patients (50%) having progressive disease as a best response (Table 3, Fig. 4D). The median PFS was 2.3 months (95% CI, 1.8–5.5) in patients with FGF19 IHC-negative tumors.

DISCUSSION

Effective treatment options for advanced HCC are limited compared with other tumor types, and there have been few biomarker-driven targeted therapies identified to date (25). Although the FGF19/FGFR4 pathway has been implicated in hepatocarcinogenesis for more than a decade, no approach has demonstrated the oncogenic importance of this pathway in human HCC to date (12,17,18). This phase I study with the highly potent and selective FGFR4 inhibitor fisogatinib clinically validates the therapeutic potential of the FGF19-FGFR4 pathway by demonstrating for the first time that FGFR4 inhibition is tolerable and efficacious in advanced HCC expressing FGF19. The findings of this study together with the identification of on-target fisogatinib resistance mutations in FGFR4 (22) confirm the driver status of the FGF19-FGFR4 pathway in HCC with FGF19 overexpression.

FGF19 overexpression is present in a notable proportion of patients with HCC; this study identified FGF19 overexpression by IHC in 27% of HCC tumor samples, consistent with previous reports (3,20). Previous nonclinical studies with monoclonal antibodies targeting the FGF19-FGFR4 pathway suggested low therapeutic index related to profound perturbations in bile acid metabolism (26); therefore, these agents did not advance in clinical testing. Our study demonstrates the feasibility and tolerability of targeting the FGF19-FGF4 pathway with a small-molecule approach. Notably, fisogatinib was tolerable across multiple dose levels that modulated the FGFR4 pathway and had antitumor activity. As expected, the most common AEs were on-target toxicities related to enhanced bile acid synthesis, including nausea, vomiting, and diarrhea. At the 600 mg QD recommended phase II dose, these events were readily managed with antiemetics and supportive care. The BID schedule had more prominent on-target toxicity and was less well tolerated, perhaps related to more continuous FGFR4 inhibition. In contrast with pan-FGFR4 inhibitors (20,27), no hyperphosphatemia was observed with fisogatinib treatment across all dose levels, confirming the exquisite selectivity of fisogatinib for FGFR4. Overall, these data indicate that selective FGFR4 inhibition via a small-molecule approach is feasible and tolerable; however, it is dependent on dose and schedule.

Fisogatinib demonstrated favorable PK properties with rapid absorption, dose-dependent PK with moderate variability, and a half-life of approximately 17 hours, supporting QD dosing. Following QD dosing, a steady-state level of fisogatinib was reached within 15 days. Accompanying PD data demonstrated that fisogatinib dose-dependently modulates the FGFR4 pathway, as evidenced by changes in circulating pathway markers (total cholesterol and FGF19). At the recommended phase II dose of 600-mg QD fisogatinib, nearly all patients had evidence of FGFR4 pathway modulation, and steady-state exposure was in the expected

therapeutic range based on nonclinical studies. Together, these data support further investigation of this dose in future studies.

Targeting FGFR4 with fisogatinib induced radiographic response per Response Evaluation Criteria in Solid Tumors version 1.1 (RECIST v1.1) in approximately 17% FGF19 IHC-positive patients and provided radiographic tumor reductions in 41% of FGF19 IHC-positive patients, regardless of their HCC etiology. This is particularly encouraging given that most patients in this study had metastatic disease, poor prognostic disease characteristics, and prior treatment with sorafenib. Previous studies with kinase inhibitors, including regorafenib, cabozantinib, brivanib, and others in the post-sorafenib setting have shown little or no response per RECIST v1.1 (4,7,28). In patients with FGF19-positive tumors, response rates to fisogatinib were similar to those reported for single-agent pembrolizumab and nivolumab in patients with HCC (5,8). The DOR and clinical benefit rate at 4 months with fisogatinib were also encouraging for the post-sorafenib setting, particularly considering that FGF19 IHC-positive patients were more likely to have poor prognostic factors, including high AFP and macrovascular invasion (MVI). In contrast with FGF19 IHC-positive patients, FGF19 IHC-negative patients had no response and little disease stabilization. Together, these data indicate that FGF19 IHC positivity increases the likelihood of response with fisogatinib and suggest that IHC positivity may be a surrogate of pathway activation.

Given the marked heterogeneity of HCC, additional translational studies with the FGF19 IHC assay and evaluation of other novel biomarkers could further optimize the selection of patients most likely to benefit from fisogatinib treatment. Notably, the level of IHC positivity was not correlated with response or genomic amplification of the FGF19 locus. This could relate to a limited dynamic range of the assay or heterogeneity of FGF19 expression across different tumor lesions. Alternatively, any level of FGF19 expression may indicate an oncogenic state driven by a minimal threshold of ligand concentration. Evaluation of tumor FGF19 RNA expression may offer a more sensitive and dynamic method for evaluating potential responders. Activation of other oncogenic pathways implicated in hepatocarcinogenesis may further modulate the response to fisogatinib (15). Interrogation of these pathways in tumor and circulating tumor DNA is feasible using next-generation sequencing. Additional studies regarding this are underway, and the results of these investigations may further refine patient selection.

In conclusion, the findings from this study of fisogatinib demonstrate for the first time that FGFR4 inhibition is tolerable and clinically active in advanced HCC expressing FGF19. PK, PD,

safety, and antitumor activity data support a continuous QD dosing schedule for fisogatinib for further clinical investigation. This study illustrates that FGFR4 signaling is targetable by small molecules for effective, biomarker-driven treatment of HCC. Based on these data and recent data suggesting enhanced efficacy with combinations of targeted therapies and checkpoint inhibitors (29-31), we are pursuing further development of fisogatinib in FGF19-positive patients both as a monotherapy and combination with immunotherapy.

METHODS

Study Design and Patients

This was a phase I, open-label, first-in-human study designed to evaluate the safety, tolerability, PK, PD, and preliminary antineoplastic activity of fisogatinib administered orally in patients with HCC. The study started in July 22, 2015, and was conducted at 21 study sites in 10 countries or territories (United States, South Korea, United Kingdom, Spain, France, Italy, China, Taiwan, Singapore, Germany, and Switzerland). For dose escalation, FGF19 IHC was assessed retrospectively. For dose expansion, FGF19 IHC was assessed prospectively to enroll ~60 IHC-positive and ~15 IHC-negative patients in expansion cohorts.

Eligible patients were ≥ 18 years of age with a confirmed HCC diagnosis per histology or noninvasive criteria guidelines (European Association for the Study of the Liver or American Association for the Study of Liver Diseases) (32) and unresectable disease; they were treatment-naïve (had declined or did not have access to sorafenib) or previously treated with sorafenib. In the dose-escalation phase, patients provided archived tumor tissue (if available) and had pre- and on-treatment tumor biopsy specimens collected if deemed appropriate by the treating physician. In the dose-expansion phase, patients had ≥ 1 target lesion per RECIST v1.1 and available FGF19 by IHC results. *FGF19* by FISH was continually measured to retrospectively stratify patients. Patients were required to have an Eastern Cooperative Oncology Group performance status of 0 or 1 and a Child-Pugh score of 5 or 6 points (class A), with no clinically apparent ascites. Patients with hepatitis C virus infection must have completed curative antiviral therapy, if indicated and available, before receiving the first dose of fisogatinib. In patients with hepatitis B virus infection, treatment with antiviral therapy was not required before enrollment and was allowed during the study, unless otherwise contraindicated with fisogatinib.

This study was conducted in accordance with the protocol, good clinical practice standards, and the Declaration of Helsinki. The appropriate Institutional Review Board or ethics committee of each participating institution approved the protocol. All enrolled patients provided written informed consent before undergoing study-specific procedures. To identify patients with FGF19-positive tumors, a separate screening Informed Consent Form was available.

Treatments

Synthesis of fisogatinib was described in the patent application WO2015/061572A1. The dose-escalation phase of the study used a 3 + 3 design in which cohorts of 3 patients received the following dose levels of oral fisogatinib on a QD schedule to determine the MTD and recommended phase II dose: 140, 280, 420, 600, and 900 mg. A second dose-escalation cohort of patients receiving fisogatinib was evaluated using a BID dosing schedule at a starting dose of 200 mg. Each cycle lasted 28 days. DLT was defined as any treatment-emergent AE of grade \geq 3 occurring during cycle 1 that was not clearly caused by something other than fisogatinib. The dose-determining population included all patients in the dose-escalation phase who received \geq 75% of fisogatinib in cycle 1 and completed cycle 1 or experienced a DLT. The dose expansion phase of the study enrolled patients who were treated with fisogatinib at the recommended phase II dose.

Endpoints

The primary objectives were to determine the MTD and recommended phase II dose of fisogatinib and to assess safety and tolerability. Secondary objectives included characterization of the PK and PD profiles, definition of FGF19 status in tumor tissue via IHC and FISH, and assessment of preliminary evidence of antitumor activity per RECIST v1.1.

Assessments

Patients without documented disease progression were followed for disease assessment approximately every 3 months until disease progression, the start of another antineoplastic therapy, or death. AEs were assessed for intensity according to the National Cancer Institute's Common Terminology Criteria for Adverse Events (NCI CTCAE), version 4.03. Treatment-emergent AEs were defined as any AE that occurred during or after administration of the first dose of fisogatinib through 30 days after the last dose of fisogatinib; any event considered related to study drug, regardless of the start date of the event; or any event that was present at

baseline but worsened in intensity or was subsequently considered related to study drug by the investigator.

Fisogatinib activity was assessed based on the ORR (defined as the rate of CR + PR) per RECIST v1.1 and the DOR. The response-evaluable population included all patients dosed in the dose-expansion phase who had measurable disease per RECIST v1.1 at baseline and ≥ 1 post-baseline disease response assessment performed on cycle 3 day 1 and received $\geq 75\%$ of fisogatinib in cycle 1.

The following PK parameters of fisogatinib were assessed as appropriate following single-dose administration and at steady state: C_{max} ; T_{max} ; AUC from 0 to 24 hours; $t_{1/2}$; apparent oral clearance (CL/F); apparent volume of distribution (V_z/F); and Rac. The following PD parameters were assessed: changes in blood including, but not limited to, changes in blood FGF19 (part 1 only); cholesterol; bile acid precursors (eg, 7 α -hydroxy-4-cholesten-3-one [cycle 4], part 1 only); AFP; and changes in tumor Ki-67 and cleaved caspase-3 levels.

IHC Assay Development

An assay using an FGF19 rabbit monoclonal antibody (clone SP268, Roche Tissue Diagnostics, Tucson, AZ) was optimized for use as a fully automated IHC assay on the BenchMark ULTRA (Roche Tissue Diagnostics) staining platform using the OptiView DAB IHC Detection Kit and OptiView Amplification Kit (Roche Tissue Diagnostics). The assay was optimized for detection of FGF19 protein expression in formalin-fixed, paraffin-embedded HCC tissue. Parameters evaluated during optimization included antibody concentration, antibody diluent, antigen retrieval method, antibody incubation conditions, and counterstain conditions. In addition, signal amplification using the OptiView Amplification Kit (Roche Tissue Diagnostics) was tested to evaluate its efficacy in visualizing specific signals. The optimal conditions for tumor cell staining in HCC tissue on the BenchMark ULTRA instrument are outlined in Supplementary Table S8. Briefly, antigen retrieval was undertaken for 16 minutes, the primary antibody was applied for 16 minutes at 36°C, and amplification was conducted for 8 minutes amplifier/8 minutes multimer. Samples were counterstained for 8 minutes with hematoxylin II and post-counterstained for 8 minutes.

Statistical Analyses

Descriptive analyses were used to characterize safety, PK, PD, and efficacy. The Kaplan-Meier method was used to estimate medians for DOR and PFS. The 95% CIs for DOR and PFS were

obtained using linear transformation. This study is registered with ClinicalTrials.gov as NCT02508467.

STUDY OVERSIGHT

This study was designed, conducted, and analyzed by Blueprint Medicines in conjunction with the authors. All authors revised and provided input to the manuscript and made the decision to submit for publication. The authors had access to all data and vouch for the validity of the study results reported herein and adherence to the protocol. The study was performed with ethical principles of the Declaration of Helsinki and was consistent with the International Conference on Harmonization/Good Clinical Practice and applicable regulatory requirements. The institutional review board or independent ethics committee of each study center approved the study.

Funding Statements

This study was funded by Blueprint Medicines.
